Chapter 4

## Observations

### 4.1 Method of Observation

All observations were made using the symmetrical beam switching mode. The data is acquired in units of 'interrupts', which correspond to the pulses which trigger the beam-switching. Each interrupt corresponds to about 0.5 seconds of integration. It is useful to divide the total integration time of an observation in sets of a number of interrupts called runs. In case there occurs a transient event that may corrupt the data, this prevents loss of the whole stretch of observation and only one run is lost. The data is integrated for a specified number of interrupts within a run, by the data-acquisition system which then transfers this integrated data to the PDP 11/84 which attaches a sub-header and appends the data-file. The sub-header contains a record of the time-varying parameters like the direction of the telescope, weather parameters, inclinometer readings etc. Typically, a run consists of 100 interrupts. The data-file is closed on finishing all the runs and writing a header which contains information like the source, observer, back-end configuration, front-end status, etc. The observing procedure is stored as a sequence of numbers in a file called.$O B S$ which is read by the control program. An example of this sequence is as follows:

$$
1,100 \begin{array}{ccc}
1,0 & 8,0 \\
\text { chopper }
\end{array} \begin{gathered}
\text { mirror }
\end{gathered} \quad 0,0
$$

The first number is the number of runs to be acquired, each consisting of the number of interrupts as specified by the second number. The last two numbers give the pointing offset in units of the beam-throw in azimuth and elevation respectively. The third and fourth numbers refer to the chopper's status and the fifth and sixth refer to the mirror's status, which are coded in the following table.

Table 1: Mirror-Chopper Codes
Code Operation

|  | Chopper |  |
| :---: | :---: | :---: |
| 0 | Sky |  |
| 1 | Hot-load |  |
| $\mathbf{2}$ | Cold load |  |
| $\mathbf{3}$ | Sky and Cold-load switching |  |
| 4 | Sky and Hot-load switching |  |
| 5 | Teflon and sky swithcing |  |
| 6 | Hot and Cold loads |  |
| 7 | Sky |  |
| Mirror |  |  |
| 8 | Sky |  |
| 9 | -4 to +4 (motor-steps) |  |
| 10 | -2 to +2 |  |
| 11 | 0 to 18 |  |
| 12 | 18 to 22 |  |
| 13 | 0 to 22 |  |
| 14 | 22 |  |
| 15 | Sky |  |

The first of the two integers, which give the mirror/chopper status, is one of the numbers in Table 1. The second is either 1 or 0 which specifies whether the mirror/chopper is in switching or 'static' mode. The operation code has this latter information but when the mirror/chopper is not switching, the data is not acquired. For getting the pulses for data-acquisition even when the mirror/chopper is in the same position, the 'static' mode is utilised, e.g., while frequency switching. While taking test runs to check the back-ends, any differences between the 'on' and 'off' beam signals in the 'static' mode will not be zero and will indicate the gain variations in the back-ends, or a DC offset in the synchronous-detector, which can then be taken into account and corrected for.

After carrying out all such sequences in the.$O B S$ file, the data-file is closed
and is ready to be used by any program for spectral-line analysis. We have used POPS (Stobie 1981) to process the data. Using beam-switching, very flat (zeroslope) baselines were obtained in almost all the spectra. In the symmetrical switching mode, one expects effects like a baseline ripple to be the same in both the positions of the tertiary corresponding to the switched beams. However, there was a residual ripple with a peak-to-peak antenna temperature of about 0.5 to 1 K . This was cancelled exactly by acquiring two spectra which were given appropriate pointing offsets in azimuth. One was with the source on the positive peak of the beam-switched response pattern in azimuth, and the other with the source on the negative peak. A superposition of these two spectra is shown in Fig. 1. On subtracting these two acquisitions (and dividing by 2) we obtained very flat baselines (see the spectra in the Appendix, where we have not applied any baseline correction.) Incidentally, this technique is useful to observe sources having small angular extent (compared to the beam), but embedded in a larger source, e.g., bipolar outflows in molecular clouds. If one is interested only in the emission from the bipolar outflow one can observe with the above procedure and cancel out the ambient emission from the molecular cloud at relatively smaller velocities. This may help in obtaining profiles with less confused wings.

Using POPS, gaussians have been fitted to the spectral-lines as mentioned in the section on Calibration in Chapter 2.

### 4.2 Selection of Sources

The observed mira variables were selected from The General Catalogue of Variable Stars (Kholopov et al., 1985). Since one of our aims was to check the hypothesis that SiO masers exist only in very late-type mira variables (with mean

Figure 1: Two beam-switched spectra acquired with offsets in azimuth, to remove the baseline ripple
spectral-type greater than M5), unlike most other observations of SiO masers, we have tried to include a substantial number of objects at spectral types earlier than M6. We have also attempted to select those objects which have been well studied at near-infra-red wavelengths, so that we can obtain information about the variation of spectral-types during pulsation? and its relation to the maser emission. Thus, we have included many objects which are common to the catalog of Lockwood (1972). To avoid very long integrations, an attempt has been made to exclude objects that are at a distance greater than 1 Kpc from the Sun.

The catalogue of 166 selected objects along with their intrinsic properties, is given in Table 2. The distribution of the number of these mira variables as a function of period, mean spectral-type and spectral-type at maximum, are * shown in Figs. 2-4. In Figs. 3 and 4, 141 stars are included. From the remaining objects, 4 belong to $S$ spectral-type, and 15 belong to $C$ type. The spectral types of remaining 6 objects are not available (some of them are infra-red stars).

### 4.3 Results

The area under the observed line-profile is obtained from,

$$
\begin{equation*}
I=\sqrt{\frac{\pi}{\ln 2}} T_{A}^{*} \Delta V, \tag{1}
\end{equation*}
$$

where $T_{A}^{*}$ and AV are the values of the antenna temperature (corrected for the atmospheric attenuation but not for the telescope losses), and the FWHM line-width in $\mathrm{km} / \mathrm{s}$, obtained by fitting a gaussian to the line-profiles. In case of multiple peaks within the profile, we have fitted gaussians to the individual peaks, where we could discern the peaks to be separate. In blended features, we have not fitted more than one gaussian. In Fig. 5, we see that the number of channels in the line-profile is large enough to allow the fitting of a gaussian.
*Comparing these with the corresponding histograms observed of the galactic Mira variables, one sees that the sample we have selected is unbiased (Kukarkin 1973).

Figure 2: Histogram of pulsational periods for the selected sources

Figure 3: Histogram of mean spectral-type for the selected sources

Figure 4: Histogram of maximum spectral-type for the selected sources

Figure 5: Fitting a gaussian to the observed line-profile
This Fig. also appears in the appendix with the full baseline

Figure 6: Detection from T Cnc

The conversion factor for antenna-temperature to Janskys, for a 10.4 m antenna, is given by $32.5 / \eta \mathrm{Jy} / \mathrm{K}$ where $\eta$ is the aperture-efficiency. As discussed in Chapter 2, we have used a mean value of $\eta=0.45$, for the observations made during 1988 and 1989. For the 1990 data, the aperture-efficiency was found to be elevation dependent (see Fig. 3.20), which we have corrected for. as listed in Table 3. Furthermore, all observations made between IST 12 hrs to 18 hrs have been corrected for a drop in the gain of the telescope, due to the heating of the dish by the Sun, as disscussed in Chapter 2 (see Fig. 3.9). After applying these corrections we obtain the flux $\mathrm{F}(\mathrm{Jy} \mathrm{km} / \mathrm{s})$, from which we obtain the photon flux (photons $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ ) , $S_{\nu}=5.03 \times 10^{-3} \mathrm{~F}$. For non-detections. we have used a mean value of $5 \mathrm{~km} / \mathrm{s}$ for the line-width, and $3 \sigma$, for an upper limit in antenna temperature, where $a$ is the r.m.s. noise in the baseline. These results are given in Table 4.

Among the positive detections, the following sources are new detections at 86 GHz (Engels 1979, Engels and Heske 1989): R Cae, T Cnc, R Crt, R Hor, RU Hya, S Vir and SW Vir. It is interesting to note that T Cnc is a C type star. In these stars the oxygen to carbon ratio is $<1$ and one expects SiO to be a less dominant silicon species compared to say SiS (Sahai, 1987), thus the presence of SiO maser in T Cnc is surprising. This detection is shown in Fig. 6. The integrated fluxes in spectral-lines from other sources are converted to luminosities in the following Chapter, and in Chapter 6, this luminosities are compared with several basic stellar-properties of the Mira variables. The observed spectral-lines, including some negative deteciion baselines are shown in the Appendix.
