(Received 21 June 2005; published 17 November 2005)

We compute the secondary cosmic microwave background radiation (CMBR) anisotropy signal from the reionization of the Universe in the presence of tangled magnetic fields. We consider the tangled-magnetic-field-induced scalar, vector, and tensor modes for our analysis. The most interesting signal for $\ell \lesssim 100$ arises from tensor perturbations. In particular, we show that the enhancement observed by Wilkinson microwave anisotropy probe (WMAP) in the TE cross-correlation signal for $\ell \lesssim 10$ could be explained by tensor TE cross correlation from tangled magnetic fields generated during the inflationary epoch for magnetic field strength $B_0 \approx 4.5 \times 10^{-9}$ G and magnetic field power spectrum spectral index $n \approx -2.9$. Alternatively, a mixture of tensor mode signal with primordial scalar modes gives weaker bounds on the value of the optical depth to the reionization surface, $\tau_{\text{reion}} \approx 0.11 \pm 0.02$. This analysis can also be translated to a limit on magnetic field strength of $\approx 5 \times 10^{-9}$ G for wave numbers $\lesssim 0.05$ Mpc$^{-1}$.

I. INTRODUCTION

Coherent magnetic field of micro-Gauss strength are observed in galaxies and clusters of galaxies ([1,2], for a recent review see e.g. [3]). Observational evidence exists for even larger scale magnetic fields [4]. The origin of these observed magnetic fields however is not well understood. The observed magnetic fields could have arisen from dynamo amplification of small seed ($\leq 10^{-20}$ G) magnetic fields (see e.g. [5,6]) which originated from various astrophysical processes in the early Universe ([3,7–12]). Alternatively the magnetic fields of nano-Gauss strength could have originated from some early Universe process like electroweak phase transition or during inflation (e.g. [13,14], see [10,15] for reviews). In this scenario, the observed micro-Gauss magnetic fields then result from adiabatic compression of this primordial magnetic field.

The existence of primordial magnetic fields of nano-Gauss strength can influence the large scale structure formation in the Universe ([16–21]). Also these magnetic fields could leave observable signatures in the CMBR anisotropies ([22–28]).

In recent years, the study of CMBR anisotropies has proved to be the best probe of the theories of structure formation in the Universe (see e.g. [29] for a recent review). The simplest model of scalar, adiabatic perturbations, generated during the inflationary era, appear to be in good agreement with both the CMBR anisotropy measurements and the distribution of matter at the present epoch (see e.g. [30,31]). Tensor perturbations could have been sourced by primordial gravitational waves during the inflationary epoch. There is no definitive evidence of the existence of tensor perturbations in the CMBR anisotropy data; the WMAP experiment, from temperature anisotropy data, obtained upper limits on the amplitude of tensor perturbations [30]. Vector perturbations are generally not considered in the standard analysis as the primordial vector perturbations would have decayed by the epoch of recombination in the absence of a source. An indisputable signal of vector and tensor modes is that unlike scalar modes these perturbations generate $B$-type CMBR polarization anisotropies (see e.g. [32] and references therein). At present, only upper limits exist on this polarization mode [33]. However, the ongoing CMBR probe WMAP and the upcoming experiment Planck surveyor have the capability of unravelling the effects of vector and tensor perturbations.

Recent WMAP results suggest that the Universe underwent an epoch of reionization at $z \approx 15$; in particular, WMAP analysis concluded that the optical depth to the last reionization surface is $\tau_{\text{reion}} \approx 0.17 \pm 0.04$ [34]; which means that nearly 20% of CMBR photons rescattered during the period of reionization. The secondary anisotropies generated during this rescattering leave interesting signatures especially in CMBR polarization anisotropies (see e.g. [35]), as is evidenced by the recent WMAP results [34].

Primordial magnetic fields source all three kinds of perturbations. In this paper we study the secondary CMBR anisotropies, generated during the epoch of reionization, from vector, tensor, and scalar modes, in the presence of primordial tangled magnetic fields. Recently, Lewis [28] computed fully numerically CMBR vector and tensor temperature and polarization anisotropies in the presence of magnetic fields including the effects of reionization. Seshadri and Subramanian [36] calculated the secondary temperature anisotropies from vector modes owing to reionization. Our approach is to compute the secondary temperature and polarization anisotropies semi-
analytically by identifying the main sources of anisotropies in each case; we compute the anisotropies by using the formalism of [32]. We also compute the tensor primary signal to compare with the already existing analytical results for tensor anisotropies [27].

In the next section, we set up the preliminaries by discussing the models for primordial magnetic fields and the process of reionization. In Section III, Section IV, and Section V, we consider tensor, vector, and scalar modes. In Section VI the detectability of the signal is discussed. In Section VII, we present and summarize our conclusions. While presenting numerical results in this paper, we use the currently favored Friedmann-Robertson-Walker model: spatially flat with $\Omega_m = 0.3$ and $\Omega_k = 0.7$ ([30,37,38]) with $\Omega_h h^2 = 0.024$ ([30,39]) and $h = 0.7$ ([40]).

II. PRIMORDIAL MAGNETIC FIELDS, REIONIZATION, AND CMBR ANISOTROPIES

Assuming that the tangled magnetic fields are generated by some process in the early Universe, e.g. during inflationary epoch, magnetic fields at large scales ($\gtrsim 0.1$ Mpc) are not affected appreciably by different processes in either the prerecombination or the post-recombination Universe ([18,21,41]). In this regime, the magnetic field decays as $1/a^2$ from the expansion of the Universe. This allows us to express: $B(x, \eta) = \hat{B}(\eta)/a^2$; here $x$ is the comoving coordinate. We further assume tangled magnetic fields $\hat{B}$, present in the early Universe, to be an isotropic, homogeneous, and Gaussian random process. This allows one to write, in Fourier space (see e.g. [42]):

$$\langle \hat{B}_i(q)\hat{B}^*_j(k) \rangle = \delta_{ij}\langle q - k \rangle (\delta_{ij} - k_i k_j/k^2) M(k).$$

(1)

Here $M(k)$ is the magnetic field power spectrum and $k = |k|$ is the comoving wave number. We assume a power-law magnetic field power spectrum here: $M(k) = A k^n$. We consider the range of scales between $k_{\min}$ and $k_{\max}$ taken to be zero here and small scale cutoff at $k = k_{\max}$ determined by the effects of damping by radiative viscosity before recombination. Following Jedamzik et al. [41], $k_{\max} = 60$ Mpc$^{-1}$ ($B_0/(3 \times 10^{-9}$ G); $B_0$ is the rms of magnetic field fluctuations at the present epoch. $A$ can be calculated by fixing the value of the rms of the magnetic field $B_0$, smoothed at a given scale $k$. Using a sharp $k$-space filter, we get

$$A = \frac{\pi^2 (3 + n)}{k^{(3+n)}} B_0^2.$$  

(2)

We take $k \sim 1$ Mpc$^{-1}$ throughout this paper. For $n = -3$, the spectral indices of interest in this paper, the rms filtered at any scale has weak dependence on the scale of filtering.

Recent WMAP observations showed that the Universe might have got ionized at redshifts $z \approx 15$. However the details of the ionization history of the Universe during the reionization era are still unknown; for instance the Universe might have gotten reionized at $z = 15$ and remained fully ionized till the present or the Universe might have got partially reionized with ionized fraction $x_e \lesssim 0.3$ at $z \approx 30$ and became fully ionized for $z \lesssim 10$. Both these ionization histories are compatible with the WMAP results [34]. Given this lack of knowledge we model the reionization history by assuming the following visibility function, which gives the normalized probability that the photon last scattered between epoch $\eta$ and $\eta + d\eta$, to model the period of reionization:

$$g(\eta, \eta_0) = \tau \exp(-\tau)$$

$$= \left(1 - \exp(-\tau_{\text{reion}})\right) \exp\left(-\frac{(\eta - \eta_{\text{reion}})^2}{\Delta \eta_{\text{reion}}^2}\right).$$

(3)

Here $\tau(\eta, \eta_0) = \int_0^\eta n_s(\sigma_\text{Th} d\eta)$ is the optical depth from Thompson scattering; $\tau_{\text{reion}}$ is the optical depth to the epoch of reionization; for compatibility with WMAP results, we use $\tau_{\text{reion}} = 0.17$ throughout. $\eta_{\text{reion}}$ and $\Delta \eta_{\text{reion}}$ are the epoch of reionization and the width of reionization phase, respectively; we take $\eta_{\text{reion}}$ corresponding to $z_{\text{reion}} = 15$ and $\Delta \eta_{\text{reion}} = 0.25 \eta_{\text{reion}}$. Notice that the visibility function is normalized to $\tau_{\text{reion}} \approx 1$.

III. CMBR ANISOTROPIES FROM VECTOR MODES

From a given wave number $k$ of vector perturbations, the contribution to CMBR temperature and polarization anisotropies to a given angular mode $\ell$ can be expressed as (see e.g. [32]):

$$\frac{\Theta^T_{k\ell}(\eta_0, k)}{(2\ell + 1)} = \int_0^{\eta_0} d\eta \exp(-\tau) \tau P'(\eta) \frac{\ell^{(11)}}{\sqrt{\Delta \eta_{\text{reion}}}}$$

$$\times \left[ k(\eta_0 - \eta) \right] + \left( \hat{\Theta} P'(\eta) + \frac{1}{\sqrt{3}} k V \right)$$

$$\times \ell^{(21)} [k(\eta_0 - \eta)].$$

(4)

$$\frac{\Theta^V_{k\ell}(\eta_0, k)}{(2\ell + 1)} = -\sqrt{6} \int_0^{\eta_0} d\eta \exp(-\tau) \tau P'(\eta) \epsilon_\ell [k(\eta_0 - \eta)].$$

(5)

$$\frac{\Theta^T_{k\ell}(\eta_0, k)}{(2\ell + 1)} = -\sqrt{6} \int_0^{\eta_0} d\eta \exp(-\tau) \tau P'(\eta) \beta_\ell [k(\eta_0 - \eta)].$$

(6)

Here $V_\ell$ and $V$ are the line-of-sight components of the vortical component of the baryon velocity and the vector metric perturbation. $P'(\eta) = 1/[10(\Theta^T_{\ell 2} - \sqrt{6} \Theta^V_{\ell 2})]$ and the Bessel functions $J_\ell$, $\epsilon_\ell$, and $\beta_\ell$ that give radial projection for a given mode are given in Appendix A ([32]). The evolution of vector metric perturbations $V_\ell(k, \eta)$ is determined from Einstein’s equations (e.g. [27,32]):
\[ \dot{V}_i + 2 \frac{a}{\dot{a}} V_i = -\frac{16 \pi G a^2 S_i(k, \eta)}{k} \]  
\[ -k^2 V_i = 16 \pi G a^2 \sum_j (\rho_j + p_j)(v_{ij}^v - V_i). \]

Here \( S_i \), the source of vector perturbations, is determined by primordial tangled magnetic field in this paper. The index \( j \) corresponds to baryonic, photons, and dark matter vortical component of velocities. For tangled magnetic fields, the vortical velocity component of the dark matter does not couple to the source of vector perturbations to linear order and \( \Omega_i = v_i^v - V_i \) decays as \( 1/a \) for dark matter (see e.g. [27]); and hence the dark matter contribution can be dropped from the Einstein’s equations. The photons couple to baryons through Thompson scattering. In the prerecombination epoch, the photons are tightly coupled to the baryons as the time scale of Thompson scattering is short as compared to the expansion rate; besides the photon density is comparable to baryon density at the epoch of recombination. In the reionized models we consider here, neither the photons are tightly coupled to baryons nor are they dynamically important. Therefore photon contribution can also be dropped from Eq. (8). Equation (8) then simplifies to:

\[ -k^2 V_i = 16 \pi G a^2 \rho_B \Omega_B^v \]  

with \( \Omega_B^v = (v_b^v - V_i) \). The quantity of interest is the angular power spectrum of the CMBR anisotropies which is obtained from squaring Eqs. (4), (5), and (6), taking ensemble average, and integrating over all \( k \):

\[ C_{T,E,B} = \frac{4}{\pi} \int dk k^2 \left[ \frac{\Theta_{T,E,B}(k, \eta_0)}{2\ell + 1} \right]^2. \]

This expression is valid for both vector and tensor perturbations; for scalar perturbation the prefactor is \( 2/\pi \).

For primordial magnetic field, the source \( S_i(k, \eta) \) of vector perturbation (Eq. (7)) is the vortical component of the Lorentz force:

\[ S_i(k, \eta) = \frac{1}{a^2 \pi} \hat{k} \text{X.F.T.} [\hat{B}(x) \times (\nabla x \hat{B}(x))] = S_i(k) \frac{1}{a^2} \]

It can be checked that this Newtonian expression for \( S_i \) is the same as the more rigorously defined \( \Pi^V_i \) in Appendix A (Eq. (A2)).

**A. Temperature anisotropies from vector modes**

As seen from Eq. (4), there are three sources of temperature anisotropies. The most important contribution comes from vorticity \( \Omega_B^v \). For the reionized models, using Eqs. (7) and (8), it can be expressed as:

\[ \Omega_B^v(k, \eta) = \frac{k S_i(k) \eta}{a \rho_{B0}}. \]

Here \( \rho_{B0} \) is the baryon density at the present epoch. The other major contribution is from temperature quadrupole \( \Theta_{T2}^2 \). For reionized models, the quadrupole at the epoch of reionization is dominated by the free streaming of the dipole from the last scattering surface (see discussion below, Eq. (15)). This contribution is generally small but in this case can be comparable to the vorticity effects at small values of \( \ell \). This is owing to the fact that the vorticity is decaying and therefore during reionization epoch its contribution is smaller as compared to the epoch of recombination. The quadrupole term on the other hand gets its contribution from the vorticity computed at the epoch of reionization (Eq. (15)). This, as we shall discuss below, is not the case for scalar and tensor anisotropies, as the dominant source of anisotropy is either constant (metric perturbations for tensor perturbations) or is increasing (compressional velocity mode for scalar perturbation) as the Universe evolves. The third source of temperature anisotropies is metric vector perturbation \( V \); this term can be comparable to the other terms only at superhorizon scales. We drop this term in this paper.

In Fig. 1 we show the secondary temperature anisotropies generated during the epoch of reionization from vector modes. It is seen that the quadrupole term has significant contribution only for \( \ell \approx 20 \). The dominant contribution at larger \( \ell \) is from the vorticity during reionization. The vorticity source contribution can be approximated as:

![FIG. 1. The secondary temperature angular power spectrum from vector modes is shown. The solid and the dashed lines correspond to the contribution from vorticity and the total signal, respectively (see text for details). The power spectrum is plotted for \( B_0 = 3 \times 10^{-9} \) and \( n = -2.9 \) (Eq. (2)).](image-url)
Here for vorticity increases roughly as $\Omega^{(1)}(k)$ reaching a value roughly close to the epoch of reionization as opposed to the first contribution which is proportional to the vorticity at the epoch of recombination. As the vorticity decays as $\sim a^{-1/2}$ in the matter-dominated era (Eq. (12)), the latter contribution is suppressed by nearly a factor of 100 in the angular power spectrum. Second, as only a small fraction of photons rescatter (nearly 20%), this contribution is further suppressed by a factor of $\tau^2_{\text{reion}}$. However, this contribution is not suppressed at small angular scales and, therefore, might dominate the polarization anisotropies at large values of $\ell$.

In Fig. 2, we show the $E$ and $B$ polarization angular power spectrum from vector modes is shown. The solid and the dot-dashed lines correspond, respectively, to the $B$- and $E$-mode contribution from the free-streaming quadrupole (Eq. (15)). The dotted and dashed curves $B$- and $E$-mode signals that arise from the source term given by Eq. (16). The power spectra are plotted for $B_0 = 3 \times 10^{-5}$ and $n = -2.9$ (Eq. (2)).

This contribution is generically smaller than the first contribution. First, this depends on the vorticity evaluated close to the epoch of reionization as opposed to the first contribution which is proportional to the vorticity at the epoch of recombination. As the vorticity decays as $a^{-1/2}$ in the matter-dominated era (Eq. (12)), the latter contribution is suppressed by nearly a factor of 100 in the angular power spectrum. Second, as only a small fraction of photons rescatter (nearly 20%), this contribution is further suppressed by a factor of $\tau^2_{\text{reion}}$. However, this contribution is not suppressed at small angular scales and, therefore,
recombination (no-reionization) and reionized scenario whereas for the polarization anisotropies we compute the secondary anisotropies by using the visibility function given by Eq. (3).

**A. Tensor temperature anisotropies**

The line-of-sight integral solution for temperature anisotropies, for tensor perturbations is given by ([32]):

$$\frac{\Theta_T(k, \eta_0)}{2\ell + 1} = \int_0^{\eta_0} d\eta e^{-\tau[\tau P_T(k, \eta)]} (\eta_0 - \eta) [22].$$

(17)

Here, \( P_T(\eta) = 1/10[\Theta_T^2 - \sqrt{6}\Theta_T^T] \) is the tensor polarization source and \( h \) is the gravitational wave contribution whose evolution is detailed in Appendix B. The polarization source is modulated by the visibility function and hence is localized to the last scattering surface. In the tight-coupling limit before recombination, \( P_T \approx -h/(3\tau) \) ([27]); for a more detailed derivation of \( P_T \) in the tight-coupling regime see Appendix B. In the postrecombination epoch, \( P_T \) is determined by the free streaming of quadrupole generated at the last scattering surface. However, the visibility function is very small at epochs prior to reionization. Therefore the main contribution of this term comes only from epochs prior to recombination. The gravitational wave source on the other hand being modulated by the cumulative visibility \( \exp(-\tau) \) contributes at all epochs. As a result, the \( P_T \) contributes negligibly to temperature anisotropies at all multipoles for the case of standard recombination. In the reionized model, this term gets additional contribution from epochs close to reionization redshift but continues to be subdominant to the other term. We have also checked this numerically. Hence we can neglect the first term in the above solution and using the matter-dominated solution for \( h \) (Appendix B) we arrive at the following expression for the angular power spectrum:

$$C_T^T = 4 \pi (\frac{4 R_s}{\rho_s})^2 (3l + 1) \int dk k^2 \frac{\Pi_{2}^2(k)}{\eta_0} \left( \int_{x_0}^{x_d} dx \exp(-\tau) \frac{j_2(x)}{x} \frac{j_d(x_0 - x)}{(x_0 - x)^2} \right)^2.$$

(18)

Here, \( x \equiv k\eta, x_0 \equiv k\eta_0, \) and \( x_d \equiv k\eta_{rec}. \) The above expression is evaluated numerically for the two different ionization histories: standard recombination with and without reionization which are essentially characterized by the different behavior of the cumulative visibility \( \exp(-\tau). \)

The temperature power spectra are shown in Fig. 3. As seen in the figure, the temperature power spectrum in both cases shows similar behavior. The power is nearly flat up to \( \ell \approx 100 \) after which the amplitude falls rapidly. This behavior is identical to that obtained for primordial gravitational waves. This is expected because the tensor metric perturbation is sourced by the magnetic field only up to the neutrino-decoupling epoch thereby imprinting an initial nearly scale-invariant spectrum after which the evolution is source free. The effect of reionization is to reduce the cumulative visibility between recombination (\( z \approx 1100 \)) and reionization (\( z \approx 15 \)) epochs. This is why the signal is suppressed for the reionized model. Approximate analytic expressions to primary \( C_T^T \) were derived in ([27]). However these give the correct qualitative behavior \( C_T^T \propto \ell^{0.2} \) only for \( \ell \leq 100 \). This is because in their analytic results, the lower limit for the time integral is taken to be zero in Eq. (18) whereas the correct lower limit is \( \eta_{rec} \) since the cumulative visibility is zero for \( \eta \approx \eta_{rec}. \) We have not neglected this lower limit in our numerical calculation and hence we obtain the damping behavior for \( \ell \geq 100; \) Lewis [28] also obtains this damping behavior. Our results are in reasonable agreement with the results of [28] in the entire range of \( \ell \); these results also agree to within factors with the results of [27] for \( \ell \leq 75 \) when the different convention we use for defining \( B_0 \) is taken into account. Our results are quantitatively accurate to better than 10% for the lower multipoles \( \ell \leq 75 \) but begin to differ appreciably from the results of numerical studies for larger \( \ell \) or in the damping regime [43]. This is because we have not treated the transition regime from radiation dominated to matter dominated for the gravitational wave evolution accurately. As described in Appendix B, we have assumed instantaneous transition. This however does not
B. Polarization anisotropies from tensor modes

The line-of-sight solution for the $E$- and $B$-mode polarization is given as:

$$\frac{\Theta_{E}^{T}(k, \eta)}{2l + 1} = -\sqrt{6} \int_{0}^{\eta} d\eta \tau \exp(-\tau) \beta_{E}^{T}[k(\eta_{0} - \eta)].$$  \hspace{1cm} (19)

$$\frac{\Theta_{E}^{T}(k, \eta)}{2l + 1} = -\sqrt{6} \int_{0}^{\eta} d\eta \tau \exp(-\tau) \epsilon_{E}^{T}[k(\eta_{0} - \eta)].$$  \hspace{1cm} (20)

Here, $\beta_{E}^{T}$ and $\epsilon_{E}^{T}$, the tensor polarization radial functions are given in Appendix A ([32]). The tensor polarization source $P^T(\eta)$ in this case will contribute significantly to the integral only close to the reionization epoch. There are two contributions to the polarization at $\eta_{\text{reion}}$; one due to the quadrupole generated at the reionization surface and the other due to the free-streaming primary quadrupole. However, as in the case of vector perturbations, the free-streaming primary quadrupole will give the dominant contribution. We thus have

$$P^T(k, \eta) = \frac{1}{10} \Theta_{E}^{T}(k, \eta)$$

$$= -\frac{1}{2} \int_{\eta_{\text{rec}}}^{\eta} d\eta \hat{n}_{\hat{z}}^{(22)}[k(\eta_{0} - \eta)] \exp(-\tau).$$  \hspace{1cm} (21)

To simplify the calculations we make the following approximation. Since the visibility function is strongly peaked at $\eta_{\text{reion}}$, we take $P^T$ outside the integral by evaluating it at the visibility peak $\eta_{\text{reion}}$. We have verified that this approximation works extremely well for the lower multipoles where the power is significant. We thus get the following expressions for the polarization angular power spectra:

$$C_{EB}^{T} = \frac{6}{\pi} \int dk k^2 \Pi_{E}^{T}(k)[P^T(\eta_{\text{reion}})]^2$$

$$\times \left( \int_{\eta_{\text{rec}}}^{\eta_{0}} d\eta \hat{n}_{\hat{z}} \epsilon^{T} \beta^{T}[k(\eta_{0} - \eta)] \right)^2.$$  \hspace{1cm} (22)

$$C_{EE}^{T} = \frac{6}{\pi} \int dk k^2 \Pi_{E}^{T}(k)[P^T(\eta_{\text{reion}})]^2$$

$$\times \left( \int_{\eta_{\text{rec}}}^{\eta_{0}} d\eta \hat{n}_{\hat{z}} \epsilon^{T} \epsilon^{T}[k(\eta_{0} - \eta)] \right)^2.$$  \hspace{1cm} (23)

As seen in the above expressions, the polarization power spectrum is modulated by the visibility function itself instead of the cumulative visibility in the case of temperature power spectrum. As a result, both $E$- as well as $B$-mode anisotropies peak close to the multipole corresponding to the horizon scale at reionization. Physically this can be understood as follows: the modes which are superhorizon at reionization experience negligible integrated Sachs-Wolfe effect before $\eta_{\text{reion}}$ and hence very small polarization is generated for such modes. Maximum polarization is generated for modes that just enter the horizon at $\eta_{\text{reion}}$. For subhorizon modes, the amplitude of the gravitational wave falls and then sets itself into oscillations which is reflected as a drop in power for higher multipoles.

The polarization power spectra are shown in Fig. 4. As seen in the figure, the $E$-mode power peaks at $\ell \sim 8$ whereas the $B$-mode power peaks at $\ell \sim 7$. The corresponding signal strengths at the peaks are $\sim 0.2 \mu K$ in both cases. As expected, the $E$-mode power is marginally greater than the $B$-mode power mainly because of the slightly different behavior of the radial projection factors.
for the primordial scalar modes, for the best-fit parameters from WMAP [30]. The power spectrum is plotted for $B_0 = 3 \times 10^{-9}$, $n = 2.9$ (Eq. (2)), and $\eta/\eta_{\text{in}} = 10^{18}$ (Eq. (B10)).

In Fig. 5 we show the expected TE cross correlation from tensor modes, computed using Eqs. (17), (20), and (28), as derived in Appendix B (Eq. (A12)). The primary power spectrum is also computed from Eqs. (22) and (23) with lower limit of the time integral replaced by zero. Our results are in agreement with the numerical results of [28] when we take into account the fact that we use different value of $\eta/\eta_{\text{in}}$ (Eq. (B10)): we use $\eta/\eta_{\text{in}} = 10^6$, which gives the epoch of generation of the tangled magnetic field close to inflationary epoch. While presenting numerical results, Lewis [28] uses $\eta/\eta_{\text{in}} = 10^8$, which puts the epoch of generation of magnetic field close to the epoch of electroweak phase transition. Therefore our signal is roughly an order of magnitude larger than the results of [28].

In addition to the vortical component of the velocity field, the tangled magnetic fields also generate compressional velocity fields which seed density perturbations. These density perturbations have interesting consequences for the formation of structures in the Universe ([16–21]). The compressional velocity field also gives rise to secondary anisotropies during the epoch of reionization. We compute this anisotropy here. The line-of-sight solution to the temperature anisotropies from these perturbations is:

$$\Theta_0^2(k, \eta_0) = \int_0^{\eta_0} \frac{d\eta}{\ell} e^{-\tau} v_s^0(k, \eta) f_{10}^{(10)}[k(\eta_0 - \eta)].$$  

Here $v_s^0$ is the line-of-sight component of the compressional velocity field, $f_{10}^{(10)}$ is defined in Appendix A ([32]). The growing mode of compressional velocity can be expressed as ([16], [20]):

$$v_s^0(k, \eta) = \frac{\eta}{4\pi \rho_{m0}} \hat{\mathbf{e}}_s \cdot \hat{\mathbf{B}}(x)(\nabla \times \mathbf{B}(x)) = v_s^0(k) \eta.$$  

Here $\rho_{m0}$ is the matter density (baryons and the cold dark matter) at the present epoch. The compressional velocity field, unlike the vortical mode, has a growing mode. Also unlike the vortical mode (Eq. (12)), the compressional mode of baryonic velocity couples to the dark matter ([20,21]). The power spectrum of compressional velocity modes is related to the density power spectrum using the continuity equation: $v_s(k, \eta) = -i \mathbf{n} \cdot \mathbf{\delta}/k^2$. The density power spectrum for magnetic field power spectrum index $n \leq -1.5$ is $\propto k^{2n+7}$ (see e.g. [20]).

In Fig. 6 we show the angular power spectrum of the secondary temperature anisotropies generated by the compressional velocity mode. The signal has a peak at roughly the angular scale that corresponds to the width of the visibility function during reionization (see e.g. [44]). This behavior is generic to the compressional velocity source which is $\propto \mathbf{n} \cdot \mathbf{v}_s^{\mathbf{B}} \propto \mathbf{n} \cdot \mathbf{k} = \mu k$ for compressional modes. As shown in [44], this leads to a suppression of the secondary anisotropies by a factor $\propto \exp(-\langle k \mu \Delta \eta_{\text{reion}} \rangle^2)$, and therefore the contribution from modes with $k \gtrsim \frac{1}{\Delta \eta_{\text{reion}}}$ is negligible. Interesting secondary signal at much smaller angular scales is possible in the second order in perturbation theory (Vishniac effect [45]), as the second order sources can give appreciable contribution for $\mu = 0$. The same is true of the vector
modes secondary anisotropies, as is seen in Fig. 1. As seen in Fig. 6, the amplitude of the compressional velocity-induced secondary anisotropies is several orders of magnitude smaller than the observed temperature anisotropies and it is unlikely that this signal could be detected.

**VI. DETECTABILITY**

It follows from Fig. 1 to 5, that the most important signal at small multipoles arises from tensor polarization anisotropies. In particular, the yet undetected $B$-mode signal holds the promise of unravelling the presence of primordial magnetic fields, as also noted by other authors (e.g. [28]). In Fig. 4, we show the expected errors on the detection of polarization signal from the future CMBR mission, Planck surveyor. The expected $1\sigma$ error, valid for $\ell \leq 100$, is (e.g. [46,47]):

$$\Delta C_\ell = \left( \frac{2}{(2\ell + 1)f_{\text{sky}}} \right) (C_\ell + w^{-1}), \quad \text{(26)}$$

for Planck surveyor $f_{\text{sky}} \approx 1$ and $w \approx 1.7 \times 10^{16}$ for one-year integration. In Fig. 4, we use the primordial tensor $B$-mode signal for calculating the expected $1\sigma$ error from Eq. (26). Figure 4 shows that the signal from magnetic fields with strength $\gtrsim 3 \times 10^{-9}$ G is detectable by this future mission. However, it is likely that, except for the $B$ mode signal, the magnetic field signal will be buried in a larger signal. However, owing to the non-Gaussianity of the magnetic field signal it might still be possible to extract this component of the signal (e.g. [28]).

In Fig. 5 we show the TE cross correlation signal from tensor modes along with the expected signal from primordial scalar modes with $\tau_{\text{reion}} = 0.17$, which is in good agreement with the WMAP data of TE cross correlation [34]. It could be asked if the TE cross correlation observed by WMAP for $\ell \leq 100$ could be explained as the tensor signal. From Fig. 5 it is seen that the tensor signal at small multipoles is roughly a factor of 5 smaller than the scalar signal. And therefore, as the power spectrum from tangled magnetic fields $\propto B_0^4$, much of the enhancement observed in the TE cross correlation for $\ell \leq 10$ could be explainable in terms of the tensor signal from primordial magnetic field $B_0 \approx 4.5 \times 10^{-9}$ G. We quantify this notion by computing the $\chi^2$ for $\ell \leq 15$ for both the best-fit model from WMAP and the tensor model with $B_0 \approx 4.5 \times 10^{-9}$ G against the detected WMAP signal [34]; the $\chi^2$ per degree of freedom in the two cases is $\approx 1.7$ and $\approx 1.8$, respectively. Therefore the enhancement can entirely be interpreted in terms of the secondary signal from primordial magnetic fields.

A more realistic possibility is that both primordial scalar and tensor modes gave comparable contribution to the observed signal. As the strength of both these signals for $\ell \leq 15$ is roughly $\approx \tau_{\text{reion}}$ (for details of secondary scalar signal see e.g. [35]), and assuming that there is roughly equal contribution from both, the inferred value of $\tau_{\text{reion}}$ from the analysis of the signal could be smaller by a factor of $\sqrt{2}$. To quantify this statement, we did a $\chi^2$ test to estimate $\tau_{\text{reion}}$ by adding the tensor signal with $B_0 \approx 4.5 \times 10^{-9}$ G and the primordial scalar signal with the best-fit cosmological parameters from WMAP. From this analysis we obtain $\tau_{\text{reion}} \approx 0.11 \pm 0.02$ (1$\sigma$) with $\sigma$ determined by $\delta \chi^2 = 1$. A possible test of this hypothesis is non-Gaussianity of the signal at small multipoles, as the magnetic field sourced tensor signal is not Gaussian.

The tensor signal (primary plus secondary) could be appreciable for $\ell \leq 100$. In the range $15 \leq \ell \leq 100$, the tensor and primordial scalar signals are nearly independent of the value of $\tau_{\text{reion}}$. While the primordial scalar TE signal anticorrelates for $\ell \geq 40$, the tensor signal shows positive cross correlation in the range $\ell \leq 100$, as seen in Fig. 5. The present WMAP data shows tentative detection of TE anticorrelation for $\ell \leq 100$ [48]. From $\chi^2$ analysis in the range $15 \leq \ell \leq 100$, we notice that the tensor signal alone is a poor fit to the data ($\chi^2$ per degree of freedom of $\approx 2.1$ as opposed to a value of 1.6 for the primordial scalar model). However a sum of these two signals with $B_0 \approx 4.5 \times 10^{-9}$ G is a reasonable fit, as it is dominated by the primordial scalar signal.

It should be noted that for $B_0 \approx 4.5 \times 10^{-9}$ G, the tensor temperature signal is comparable to the primordial scalar

---

signal (Fig. 3). WMAP analysis obtained an upper limit of \( \approx 0.7 \) on the ratio of tensor to scalar signal ([30]). While this limit is rather weak, a more detailed analysis of the temperature signal including the effect of tensor mode signal sourced by primordial magnetic fields might give independent constraints on the strength of primordial magnetic fields.

In our \( \chi^2 \) analysis we use only the diagonal components of the Fisher matrix. However, owing to incomplete sky, the signal is correlated, especially for small multipoles, across neighboring multipoles. However, a more comprehensive analysis taking into this correlation is likely to yield similar conclusions for the reasons stated above.

Our conclusions are not too sensitive to the value of small scale cutoff \( k_{\text{max}} \) or the scale of the filter \( k_c \) used to define the normalization (Eq. (2)) for magnetic field power spectrum index \( n = -2.9 \) we use throughout the paper. For \( k_{\text{max}} = k_c = 0.05 \text{ Mpc}^{-1} \), the foregoing discussion related to tensor mode anisotropies would be valid for \( B_0 \approx 5 \times 10^{-9} \text{ G} \). Therefore, the results for TE cross correlation from tensor perturbations can be interpreted to put bounds on magnetic fields for only large scales \( k \lesssim 0.05 \text{ Mpc}^{-1} \).

The strongest bound on primordial magnetic fields arises from tensor perturbations in the prerecombination era [49]. These bounds are weakest for nearly scale-invariant \((n \approx -3)\) magnetic fields power spectrum (Eq. (33) of [49]) and largely motivated the choice of the power spectral index we consider here. For \( n = -2.9 \), the bound obtained by [49] is considerably weaker than \( B_0 \approx 4.5 \times 10^{-9} \text{ G} \), the values of interest to us in this paper. Vector modes might leave observable signature in the temperature and polarization signal for \( \ell \approx 2000 \); the current observations give weak bound of \( B_0 \approx 8 \times 10^{-9} \text{ G} \) [28]. Tangled magnetic field sourced primary scalar temperature signal gives even weaker bounds [50]. More recently, Chen et al. [51] obtained, from WMAP data analysis, a limit of \( \approx 10^{-8} \text{ G} \) on the primordial magnetic field strength for nearly scale-invariant spectra we consider here; [51] consider vector-mode temperature signal in their analysis and study possible non-Gaussianity in the WMAP data. Another strong constraint on large scale tangled magnetic fields comes from Faraday rotation of high redshift radio sources (see e.g [3]); this constraint is also weaker than the value of magnetic field required to explain the enhancement of the TE cross-correlation signal as seen by WMAP [19].

Another interesting bound on the strength of tangled magnetic fields during the reionization epoch arises from the Zeeman splitting of 21 cm radiation from the epoch of reionization [52]; this results in a bound on the magnetic field strength of \( \approx 100\mu\text{G} \) coherent over megaparsec scales. Therefore, the value of \( B_0 \) required to give appreciable contribution to the TE signal is well within the upper limits on \( B_0 \) from other considerations.

It should be noted that the entire foregoing discussion on the tangled magnetic field tensor signal can be mapped to primordial tensor modes. The reason for this assertion is that magnetic fields source tensor modes only prior to the epoch of neutrino decoupling, and the subsequent evolution is source free, which is similar to the primordial tensor modes which are generated only during the inflationary epoch and evolve without sources at subsequent times. Therefore, an analysis similar to ours could be used to put constraints on the relative strength of the tensor to scalar mode contribution (for a fixed scale) and the tensor spectral index of the primordial modes. The main observational difference between such an interpretation and the one given here is that tensor signal sourced by magnetic fields will not obey Gaussian statistics as opposed to the primordial tensor modes.

### VII. SUMMARY AND CONCLUSIONS

We have computed the secondary anisotropies from the reionization of the Universe in the presence of tangled primordial magnetic fields. Throughout our analysis we use the nearly scale-invariant magnetic field power spectrum with \( n = -2.9 \). For vector modes, we compute the secondary temperature and \( E- \) and \( B- \) mode polarization autocorrelation signal. For scalar modes, the results for secondary temperature angular power spectrum from compressional velocity modes are presented. For tensor modes, in addition to the secondary temperature and polarization angular power spectra, we compute the TE cross correlation signal and compare it with the existing WMAP data; we also recompute the primary signal for tensor modes. Whenever possible we compare our results with the results existing in the literature. In particular, Lewis [28] recently computed fully numerically the vector and tensor primary and secondary temperature and polarization power spectra. We compare our semianalytic results with this analysis and find good agreement. Seshadri and Subramanian [36] computed the secondary temperature anisotropies from vector modes. Our results are in good agreement with their conclusion. Mack et al. [27] computed primary signal from vector and tensor modes using the formalism we adopt in this paper. Our results are in disagreement with their results for \( \ell \approx 75 \), and we have given reasons for our disagreement in the discussion above. In addition to comparison with existing literature, we also give new results for secondary TE cross correlation from tensor modes and secondary temperature angular power spectrum from scalar modes.

We discuss below the details of expected signal from each of the perturbation mode:

- **Vector modes:** The secondary temperature and polarization signals from the vector modes is shown in Fig. 1 and 2. The secondary temperature signal increases \( \propto \ell^{2.4} \) for \( \ell \geq 50 \) and reaches a value \( \approx 0.1(\mu \text{k})^2 \) for \( \ell \approx 10^4 \), in agreement with the analysis of [36]. For small \( \ell \) the signal is very small\( (\approx 10^{-4}(\mu \text{k})^2) \) and for large \( \ell \) the secondary signal is smaller than the primary signal (e.g. [28]) and
therefore it is unlikely that the signature of reionization could be detected in the vector-mode temperature anisotropies. The polarization signal, shown in Fig. 2, is sourced by the free streaming of dipole at the epoch of recombination. This signal dominates the primary signal for \( \ell \lesssim 10 \), but is several orders of magnitude smaller than the expected signal from tensor modes.

**Scalar modes:** We only compute the secondary temperature anisotropies from compressional velocity modes in this case. As seen in Fig. 6, this contribution is several orders of magnitude smaller than the already-detected primary signal and therefore its effects are unlikely to be detectable.

**Tensor modes:** As seen from Figs. 4 and 5, the most interesting CMBR anisotropy signal for \( \ell \lesssim 100 \) is from these modes. The secondary B-mode signal from tensor modes is detectable by future CMBR mission Planck surveyor for \( B_0 \approx 3 \times 10^{-9} \) G. The tensor TE cross correlation from primordial magnetic fields can explain the observed enhancement of the observed signal for \( \ell \lesssim 10 \) by WMAP for \( B_0 \approx 4.5 \times 10^{-9} \) G if the primordial magnetic fields are generated during the epoch of inflation. Assuming that tensor modes make a significant contribution to the observed enhancement, the bounds on the optical depth to the surface of reionization \( \tau_{\text{reion}} \) are weaker by roughly a factor of \( \sqrt{2} \). This hypothesis can be borne/ruled out by testing the Gaussianity of the signal for \( \ell \lesssim 10 \).

**ACKNOWLEDGMENTS**

We would like to thank A. Lewis for prompt reply to our queries and to T.R. Seshadri and K. Subramanian for useful discussion.

**APPENDIX A**

In this section, we briefly discuss the terminology and present the complete expressions for the vector and tensor power spectra \( \Pi^V(k) \) and \( \Pi^T(k) \) [27]. The energy-momentum tensor for magnetic fields for a single Fourier mode is a convolution of different Fourier modes and is given by:

\[
T_{ij}(k) = \int d^3q \left[ \hat{B}_i(q) \hat{B}_j(k - q) - \frac{1}{2} \delta_{ij} \hat{B}_m(q) \hat{B}_m(k - q) \right].
\]  
(A1)

The energy-momentum tensor has nonvanishing scalar, vector, and tensor components. The vector and tensor components, in Fourier space, are defined as:

\[
\Pi^V_{ij} = P_{ij} \hat{k}_q T_{pq},
\]  
(A2)

\[
\Pi^T_{ij} = \left( P_{ij} P_{pq} - \frac{1}{2} P_{ij} P_{pq} \right) T_{pq}.
\]  
(A3)

Here \( P_{ij} = \delta_{ij} - \hat{k}_i \hat{k}_j \). The vector and tensor anistropic stress are then defined as the two-point correlations of the above components as:

\[
\langle \Pi^V_{ij}(k) \Pi^V_{ij}(k') \rangle = 2 |\Pi^V(k)|^2 \delta(k + k'),
\]  
(A4)

\[
\langle \Pi^T_{ij}(k) \Pi^T_{ij}(k') \rangle = 4 |\Pi^T(k)|^2 \delta(k + k').
\]  
(A5)

By evaluating the above correlations as also given in [27], we can arrive at the following approximate expression for the power spectra for \( n < -3/2 \):

\[
|\Pi^V(k)|^2 = \frac{A^2}{64 \pi^4(n + 3)} k^{2n+3}.
\]  
(A6)

\[
|\Pi^T(k)|^2 = \frac{2A^2}{64 \pi^4(n + 3)} k^{2n+3}.
\]  
(A7)

Here, \( A \) is the normalization of the magnetic power spectrum given in Eq. (2).

**1. Bessel functions**

We give below a list of all the relevant spherical Bessel functions we have used in the foregoing text. These are taken from Ref. [32]. For the vector-mode temperature anisotropies, the relevant spherical Bessel functions are:

\[
\begin{align*}
J^{(11)}_\ell &= \frac{\ell(\ell + 1) j_\ell(x)}{2x}, \\
J^{(21)}_\ell &= \frac{3\ell(\ell + 1) d}{2} \frac{j_\ell(x)}{dx}.
\end{align*}
\]  
(A8)

(A9)

For vector-induced polarization anisotropies, the spherical Bessel functions of interest are:

\[
\begin{align*}
\epsilon^{\ell}_\ell &= \frac{1}{2} \sqrt{(\ell - 1)(\ell + 2)} \left[ j_\ell(x) + \frac{j'_\ell(x)}{x} \right] , \\
\beta^{\ell}_\ell &= \frac{1}{2} \sqrt{(\ell - 1)(\ell + 2)} \frac{j_\ell(x)}{x}.
\end{align*}
\]  
(A10)

(A11)

Here prime denotes a derivative with respect to \( x \). For tensor-induced temperature and polarization anisotropies, the relevant Bessel functions are:

\[
\begin{align*}
J^{(22)}_\ell &= \frac{3(\ell + 2)!}{8(\ell - 2)!} \frac{j_\ell(x)}{x^2}, \\
\beta^{\ell}_\ell &= \frac{1}{2} \left[ j_\ell(x) + \frac{2j'_\ell(x)}{x} \right].
\end{align*}
\]  
(A12)

(A13)

\[
\begin{align*}
\epsilon^{\ell}_\ell &= \frac{1}{4} \left[ -j_\ell(x) + j''_\ell(x) + \frac{2j_\ell(x)}{x^2} + \frac{4j'_\ell(x)}{x} \right].
\end{align*}
\]  
(A14)

For scalar modes, the Bessel function of interest for
velocity-induced perturbations is:

\[ j^{(10)}_\ell = j^{(1)}_\ell(x). \quad (A15) \]

### APPENDIX B

Gravitational waves correspond to transverse, traceless perturbations to the metric: \( \delta g_{ij} = 2a^2(\eta)h_{ij} \) with \( h_{ij} = \tilde{\epsilon}_{ij} = 0 \). Since \( h_{ij} \) is a stochastic variable we can define its power spectrum as:

\[ \langle h_{ij}(\mathbf{k}, \eta)h_{ij}(\mathbf{k}', \eta) \rangle = 4|\langle \delta(h, \eta) \rangle|^2 \delta(\mathbf{k} + \mathbf{k}') \quad (B1) \]

The evolution of \( h_{ij} \) then follows from the tensor Einstein equation (see e.g. [32])

\[ \ddot{h} + 2\frac{\dot{a}}{a} \dot{h} + k^2 h = 8\pi GS(k, \eta). \quad (B2) \]

The source on the right-hand side (RHS) is the tensor anisotropic stress of the plasma which is defined as:

\[ S(k, \eta) = \Pi^T(k)/a^2 \quad (\text{Eq. (A5)}) \]

where \( \Pi^T(k) \) is the magnetic tensor anisotropic stress as defined in Eq. (A5). We now derive the solutions to Eq. (B2) in various regimes. The evolution of the scale factor \( a(\eta) \) is given by the Friedmann equation:

\[ \dot{a}^2 = \frac{8\pi}{3} \sum \rho_i + \Omega_\Lambda a^2. \quad (B3) \]

Here, \( \Omega_m, \Omega_\gamma, \Omega_\Lambda \) are the fractional densities in matter, radiation, neutrinos, and cosmological constant, respectively. Approximate solutions in the radiation-dominated and matter-dominated epoch are \( a(\eta) = 2\sqrt{\Omega_\gamma/\eta} \) and \( a(\eta) = \left( \frac{\rho_\gamma}{\rho_\gamma} \right)^{1/2} \), respectively. Using the above form for the scale factor we can rewrite Eq. (B2) for \( \eta_{in} < \eta < \eta_\ast \) as:

\[ \ddot{h} + 2\frac{\dot{a}}{a} \dot{h} + k^2 h = \frac{3R_s \Pi^T(k)}{\rho_\gamma} \frac{1}{\eta^2}. \quad (B4) \]

Here, \( R_\gamma = \Omega_\gamma/(\Omega_\gamma + \Omega_\nu) \approx 0.6 \). \( \rho_\gamma \) is the CMBR energy density. Equation (B4) can be solved exactly using the Green’s function technique to give [27]:

\[ h(k, \eta) = \frac{3R_s \Pi^T(k)}{\rho_\gamma} \int_{\eta_{in}}^\eta d\eta' \sin[k(\eta - \eta')]/\eta'. \quad (B5) \]

For superhorizon modes \( k\eta \ll 1 \), the above form can be simplified to give:

\[ h(k, \eta) \approx \frac{3R_s \Pi^T(k)}{\rho_\gamma} \int_{\eta_{in}}^\eta d\eta' k(\eta - \eta')/k\eta^2 = \frac{3R_s \Pi^T(k)}{\rho_\gamma} \ln\left( \frac{\eta}{\eta_{in}} \right). \quad (B6) \]

For \( \eta \gg \eta_\ast \), the evolution of \( h \) is given by the homogeneous solutions in the radiation and matter-dominated regimes:

\[ h_{rad}(k, \eta) = A_1j_0(k\eta), \quad (B7) \]

\[ h_{mat}(k, \eta) = A_2j_1(k\eta)/k\eta. \quad (B8) \]

The coefficients \( A_1 \) and \( A_2 \) are determined by matching the superhorizon solutions at the two transitions \( \eta_\ast \) and \( \eta_{eq} \). We thus get

\[ A_2 = 3A_1 = \frac{9R_s \Pi^T(k)}{\rho_\gamma} \ln\left( \frac{\eta_{eq}}{\eta_{in}} \right). \quad (B9) \]

Thus, the full expression for the matter-dominated solution can be written as:

\[ h_{mat}(\eta, k) = \frac{9R_s \Pi^T(k)}{\rho_\gamma} \ln\left( \frac{\eta_{eq}}{\eta_{in}} \right) j_1(k\eta)/\eta. \quad (B10) \]

This solution is used for solving tensor temperature and polarization primary and secondary anisotropies. Few assumptions have been made in deriving the above expression. First, the transition between radiation-dominated to matter-dominated region has been assumed to be instantaneous. This however does not affect the evolution of modes with wavelength greater than the width of transition \( k\eta_{eq} \ll 1 \). Moreover, only superhorizon solutions have been used to match the solutions for \( h \) at different transitions. These simplifications however do not affect the results quotes for small multipoles as discussed in the main section.

### 1. Tight-coupling tensor quadrupole

In the tight-coupling regime \( z \approx 1100 \) to lowest order in mean-free path, we have \( P^T = -\dot{h}/(3\dot{\tau}) \) [27]. We however use the expression accurate to the second order in mean-free path as is done for the scalar modes in [53]. Using the Boltzmann equation for the evolution of tensor modes we get the following equation for \( P^T(k, \eta) \) in the tight-coupling limit:

\[ \dot{P} + \frac{3}{10} \dot{\tau}P = -\frac{\dot{h}}{10\dot{\tau}}. \quad (B11) \]

The lowest order solution to this equation is obtained by neglecting the \( P \) in the equation, which gives \( P = -\dot{h}/(3\dot{\tau}) \). The above equation however can be solved exactly to give:

\[ P(\eta) = \int_0^\eta d\eta' h\dot{\epsilon}e^{-(3/10)(\tau(\eta') - \tau(\eta))}. \quad (B12) \]

We use the standard recombination history for computing \( \tau \).
